Abstract. We consider a differential model describing neuro-physiological contrast perception phenomena induced by surrounding orientations. The mathematical formulation relies on a cortical-inspired modelling [11] largely used over the last years to describe neuron interactions in the primary visual cortex (V1) and applied to several image processing problems [14,21,15]. Our model connects to Wilson-Cowan-type equations [26] and it is analogous to the one used in [4,3,16] to describe assimilation and contrast phenomena, the main novelty being its explicit dependence on local image orientation. To confirm the validity of the model, we report some numerical tests showing its ability to explain orientation-dependent phenomena (such as grating induction) and geometric-optical illusions [24,18] classically explained only by filtering-based techniques [7,20].

· Primary Visual Cortex · Contrast Perception · Variational modelling

1 Introduction

Many, if not most, popular vision models consist in a cascade of linear and non-linear (L+NL) operations [17]. This happens for models describing both visual perception – e.g., the Oriented Difference Of Gaussians (ODOG) [7] or the Brightness Induction Wavelet Model (BIWaM) [20] – and neural activity [10]. However, L+NL models, while suitable in many cases for retinal and thalamic activity, are not adequate to predict neural activity in the primary visual cortex area (V1). In fact, according to [10], such models have low predictive power (they can explain less than 40% of the variance of the data). On the other hand, several vision models are not in the form of a cascade of L+NL operations, such

as those describing neural dynamics via Wilson-Cowan (WC) equations [26,9]. These equations describe the state $a(x, \theta, t)$ of a population of neurons with V1 coordinates $x \in \mathbb{R}^2$ and orientation preference $\theta \in [0, \pi)$ at time $t > 0$ as

$$\frac{\partial}{\partial t} a(x, \theta, t) = -\alpha a(x, \theta, t) + \nu \int_0^\pi \int_{\mathbb{R}^2} \omega(x, \theta \| x', \theta') \sigma(a(x', \theta', t)) dx' d\theta' + h(x, \theta, t). \quad (1)$$

Here, $\alpha, \nu > 0$ are fixed parameters, $\omega(x, \theta \| x', \theta')$ is an interaction weight, $\sigma : \mathbb{R} \rightarrow \mathbb{R}$ is a sigmoid saturation function and h represents the external stimulus. In [4,5,3] the authors show how orientation independent WC-type equations admit a variational formulation through an associated energy functional which can be linked to histogram equalisation, visual adaptation and efficient coding [19].

In this paper, we consider a generalisation of this modelling and introduce explicit orientation dependence via a lifting procedure inspired by neuro-physiological models of V1 [11,14,21]. Interestingly, the Euler-Lagrange equations associated with the proposed functional yield orientation-dependent WC-type equations analogous to (1). We remark that WC-type cortical-inspired models have been previously considered in [1,22], though without any variational interpretation and with only very few applications to contour detection for spatio-temporal imaging. The numerical results of our enriched variational model show how it can effectively be applied to reproduce more elaborated visual perception phenomena in comparison to both previous orientation-independent WC-type models and state-of-the-art ODOG [7] and BIWaM [20] L+NL models.

We firstly test our model on orientation-dependent Grating Induction (GI) phenomena (generalising the ones presented in [7, Figure 3], see also [18]) and show a direct dependence of the processed image on the orientation, which cannot be reproduced via orientation-independent models, but which is in accordance with the reference result provided by the ODOG model. We then test the proposed model on the Poggendorff illusion, a geometrical optical effect where a misalignment of two collinear segment is induced by the presence of a surface [24,25], see Figure 6. For this example our model is able to reconstruct the perceptual bias better than all the reference models considered.

2 Orientation-independent variational models

Let $Q \subset \mathbb{R}^2$ be a rectangular image domain and let $f : Q \rightarrow [0, 1]$ be a normalised image on Q . Let further $\omega : Q \times Q \rightarrow \mathbb{R}_+$ be a given positive symmetric weighting function such that for any $x \in Q$, $\omega(x, \cdot) \in L^1(Q)$. For a fixed parameter $\alpha > 1$ we consider the piecewise affine sigmoid $\sigma_\alpha : \mathbb{R} \rightarrow [-1, 1]$ defined by $\sigma_\alpha(\rho) := \min\{1, \max\{\alpha\rho, -1\}\}$, and Σ_α to be any function such that $\Sigma'_\alpha = \sigma_\alpha$. Trivially, the function Σ_α is convex and even.

In [4,3,16] the authors consider the following energy as a variational model for contrast and assimilation phenomena, defined for a given initial image f_0 :

$$\begin{aligned} \mathcal{E}(f) := & \frac{1}{2} \int_Q (f(x) - \mu(x))^2 dx + \frac{\lambda}{2} \int_Q (f(x) - f_0(x))^2 dx \\ & - \frac{1}{4M} \int_Q \int_Q \omega(x, y) \Sigma_\alpha(f(x) - f(y)) dx dy. \end{aligned} \quad (2)$$

Here, $\mu : Q \rightarrow \mathbb{R}$ is the local mean of the initial image f_0 . Such term can encode a global reference to the “Grey-World” principle [4] (in this case $\mu(x) = \frac{1}{2}$ for any $x \in Q$), or a filtering around $x \in Q$ computed either via a single-Gaussian convolution [3] or a sum of Gaussian filters [16], consistently with the modelling of the multiple inhibition effects happening at a retinal-level [27]. Finally, the parameter $M \in (0, 1]$ stands for a normalisation constant, while $\lambda > 0$ represents a weighting parameter enforcing the attachment of the solution f to f_0 .

The gradient descent associated with \mathcal{E} corresponds to a Wilson-Cowan-type equation similar to (1), where the visual activation is assumed to be independent of the orientation, as discussed in [8]. The parameters α and ν are set $\alpha = 1$ and $\nu = \frac{1}{2M}$ and the time-invariant external stimulus h is equal to $\mu + \lambda f_0$:

$$\frac{\partial}{\partial t} f(x, t) = -(1+\lambda)f(x, t) + (\mu(x) + \lambda f_0(x)) + \frac{1}{2M} \int_Q \omega(x, y) \sigma_\alpha(f(x, t) - f(y, t)) dy. \quad (3)$$

Note that in [16] the authors consider in (2) a convolution kernel ω which is a convex combination of two 2D Gaussians with different standard deviations. While this variation of the model is effective in describing *assimilation* effects, the lack of dependence on the local perceived orientation in (3) makes such modelling intrinsically not adapted to orientation-induced contrast/colour perception effects as the ones observed in [20,23,7]. Up to our knowledge, the only perceptual models capable to explain the latter are the ones based on oriented Difference of Gaussian filtering coupled with some non-linear processing, such as the ODOG and the BIWaM models described in [7,6] and [20], respectively.

3 A cortical-inspired model

Let us denote by $R > 0$ the size of the visual plane and let $D_R \subset \mathbb{R}^2$ be the disk $D_R := \{x_1^2 + x_2^2 \leq R^2\}$. Fix $R > 0$ such that $Q \subset D_R$. In order to exploit the properties of the roto-translation group $SE(2)$ on images, we now consider them to be elements in the set: $\mathcal{I} = \{f \in L^2(\mathbb{R}^2, [0, 1]) \text{ such that } \text{supp } f \subset D_R\}$. We remark that fixing $R > 0$ is necessary, since contrast perception is strongly dependent on the scale of the features under consideration w.r.t. the visual plane.

In the following, after introducing the functional lifting under consideration, which follows well-established ideas contained, e.g., in [11,14,21], we present the proposed cortical-inspired extension of the energy functional (2), and discuss the numerical implementation of the associated gradient descent. We remark that the resulting procedure thus consists of a linear lifting combined with WC-type evolution, which is non-linear due to the presence of the sigmoid σ_α , see (??).

3.1 Functional lifting

Each neuron ξ in V1 is assumed to be associated with a receptive field (RF) $\psi_\xi \in L^2(\mathbb{R}^2)$ such that its response under a visual stimulus $f \in \mathcal{I}$ is given by

$$F(\xi) = \langle \psi_\xi, f \rangle_{L^2(\mathbb{R}^2)} = \int_{\mathbb{R}^2} \overline{\psi_\xi(x)} f(x) dx. \quad (4)$$

Motivated by neuro-physiological evidence, we assume that each neuron is sensible to a preferred position and orientation in the visual plane, i.e., $\xi = (x, \theta) \in \mathcal{M} = \mathbb{R}^2 \times \mathbb{P}^1$. Here, \mathbb{P}^1 is the projective line that we represent as $[0, \pi]/\sim$, with $0 \sim \pi$. Moreover, we assume that RFs of different neurons are “deducible” one from the other via a linear transformation. Let us explain this in detail.

The double covering of \mathcal{M} is given by the Euclidean motion group $SE(2) = \mathbb{R}^2 \rtimes \mathbb{S}^1$, that we consider endowed with its natural semi-direct product structure

$$(x, \theta) \star (y, \varphi) = (x + R_\theta y, \theta + \varphi), \quad \forall (x, \theta), (y, \varphi) \in SE(2), \quad R_\theta = \begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}.$$

In particular, the above operation induces an action of $SE(2)$ on \mathcal{M} , which is thus an homogeneous space. Observe that $SE(2)$ is unimodular and that its Haar measure (the left and right-invariant measure up to scalar multiples) is $dx d\theta$.

We now denote by $\mathcal{U}(L^2(\mathbb{R}^2)) \subset \mathcal{L}(L^2(\mathbb{R}^2))$ the space of linear unitary operators on $L^2(\mathbb{R}^2)$ and let $\pi : SE(2) \rightarrow \mathcal{U}(L^2(\mathbb{R}^2))$ be the *quasi-regular representation* of $SE(2)$ which associates to any $(x, \theta) \in SE(2)$ the unitary operator $\pi(x, \theta) \in \mathcal{U}(L^2(\mathbb{R}^2))$, i.e., the action of the roto-translation (x, θ) on square-integrable functions on \mathbb{R}^2 . Namely, $\pi(x, \theta)$ acts on $\psi \in L^2(\mathbb{R}^2)$ by

$$[\pi(x, \theta)\psi](y) = \psi((x, \theta)^{-1}y) = \psi(R_{-\theta}(y - x)), \quad \forall y \in \mathbb{R}^2.$$

Moreover, we let $\Lambda : SE(2) \rightarrow \mathcal{U}(L^2(SE(2)))$ be the *left-regular representation*, which acts on functions $F \in L^2(SE(2))$ as

$$[\Lambda(x, \theta)F](y, \varphi) = F((x, \theta)^{-1} \star (y, \varphi)) = F(R_{-\theta}(y - x), \varphi - \theta), \quad \forall (y, \theta) \in SE(2).$$

Letting $L : L^2(\mathbb{R}^2) \rightarrow L^2(\mathcal{M})$ be the operator that transforms visual stimuli into cortical activations, it is natural to require that

$$L \circ \pi(x, \theta) = \Lambda(x, \theta) \circ L, \quad \forall (x, \theta) \in SE(2).$$

Under mild continuity assumption on L , it has been shown in [21] that L is then a continuous wavelet transform. That is, there exists a *mother wavelet* $\Psi \in L^2(\mathbb{R}^2)$ satisfying $\pi(x, \theta)\Psi = \pi(x, \theta + \pi)\Psi$ for all $(x, \theta) \in SE(2)$, and such that

$$Lf(x, \theta) = \langle \pi(x, \theta)\Psi, f \rangle, \quad \forall f \in L^2(\mathbb{R}^2), (x, \theta) \in \mathcal{M}. \quad (5)$$

Observe that the operation $\pi(x, \theta)\Psi$ above is well defined for $(x, \theta) \in \mathcal{M}$ thanks to the assumption on Ψ . By (4), the above representation of L is equivalent to the fact that the RF associated with the neuron $(x, \theta) \in \mathcal{M}$ is the roto-translation of the mother wavelet, i.e., $\psi_{(x, \theta)} = \pi(x, \theta)\Psi$.

Remark 1. Letting $\Psi^*(x) := \overline{\Psi(-x)}$, the above formula can be rewritten as

$$Lf(x, \theta) = \int_{\mathbb{R}^2} \overline{\Psi(R_{-\theta}(y-x))} f(y) dy = [f * (\Psi^* \circ R_{-\theta})](x),$$

where $f * g$ denotes the standard convolution on $L^2(\mathbb{R}^2)$.

Notice that, although images are functions of $L^2(\mathbb{R}^2)$ with values in $[0, 1]$, it is in general not true that $Lf(x, \theta) \in [0, 1]$. However, from (5) we deduce that Lf is a continuous function, satisfying $|Lf| \leq \|\Psi\|_{L^2(\mathbb{R}^2)} \|f\|_{L^2(\mathbb{R}^2)}$.

Neuro-physiological evidence shows that a good fit for the RFs is given by Gabor filters, whose Fourier transform is the product of a Gaussian with an oriented plane wave [12]. However, these filters are quite challenging to invert, and are parametrised on a bigger space than \mathcal{M} , which takes into account also the frequency of the plane wave and not only its orientation. For this reason, in this work we chose to consider as wavelets the *cake wavelets* introduced in [13], see also [2]. These are obtained via a mother wavelet Ψ^{cake} whose support in the Fourier domain is concentrated on a fixed slice, depending on the number of orientations one aims to consider in the numerical implementation. For the sake of integrability, the Fourier transform of this mother wavelet is then smoothly cut off via a low-pass filtering, see [2, Section 2.3] for details. Observe, however, that in order to lift to \mathcal{M} and not to $SE(2)$, we consider a non-oriented version of the mother wavelet, given by $\tilde{\psi}^{\text{cake}}(\omega) + \tilde{\psi}^{\text{cake}}(e^{i\pi}\omega)$, in the notations of [2].

An important feature of cake wavelets is that, in order to recover the original image, it suffices to define the so-called *projection operator* by

$$P : L^2(\mathcal{M}) \rightarrow L^2(\mathbb{R}^2), \quad PF(x) := \int_{\mathbb{P}^1} F(x, \theta) d\theta, \quad F \in L^2(\mathcal{M}) \quad (6)$$

Indeed, by construction of cake wavelets it holds that $\int_{\mathbb{P}^1} R_\theta \Psi^{\text{cake}} d\theta = 1$ and thus a straightforward application of Fubini's Theorem shows that $P \circ L = \text{Id}$.

3.2 WC-type mean field modelling

The natural extension of (2) to the cortical setting introduced in the previous section is the following energy on functions $F \in L^2(\mathcal{M})$:

$$\begin{aligned} \mathcal{E}(F) = & \frac{1}{2} \|F - G_0\|_{L^2(\mathcal{M})}^2 + \frac{\lambda}{2} \|F - F_0\|_{L^2(\mathcal{M})}^2 \\ & - \frac{1}{4M} \int_{\mathcal{M}} \int_{\mathcal{M}} \omega(x, \theta \| x', \theta') \Sigma_\alpha(F(x, \theta) - F(x', \theta')) dx d\theta dx' d\theta'. \end{aligned} \quad (7)$$

Here, G_0 is the lift $L\mu$ of the local mean appearing in (2), and F_0 is the lift Lf_0 of the given initial image f_0 . The constant $M \in (0, 1]$ will be specified later. Furthermore, $\omega : \mathcal{M} \times \mathcal{M} \rightarrow \mathbb{R}_+$ is a positive symmetric weight function and, as in [4], we denote by $\omega(x, \theta \| x', \theta')$ its evaluation at $((x, \theta), (x', \theta'))$. A sensible choice for ω would be an approximation of the heat kernel of the anisotropic diffusion

associated with the structure of V1, as studied in [11,14]. However, in this work we restrict to the case where $\omega(x, \theta \| x', \theta') = \omega(x - x', \theta - \theta')$ is a (normalised) 3D Gaussian in \mathcal{M} , since this is sufficient to describe many perceptual phenomena not explained by the previous 2D model (2). A possible improvement could be obtained by choosing ω as the sum of two such Gaussians at different scales in order to better describe, e.g., lightness assimilation phenomena.

Thanks to the symmetry of ω and the oddness of σ , computations similar to those of [4] yield that the gradient descent associated with (7) is

$$\begin{aligned} \frac{\partial}{\partial t} F(x, \theta, t) = & -(1 + \lambda)F(x, \theta, t) + G_0(x, \theta) + \lambda F_0(x, \theta) \\ & + \frac{1}{2M} \int_{\mathcal{M}} \omega(x, \theta \| x', \theta') \sigma_{\alpha}(F(x, \theta, t) - F(x', \theta', t)) dx' d\theta'. \end{aligned} \quad (8)$$

This is indeed a Wilson-Cowan-type equation, where the external cortical stimulus h in (1) is $h = G_0 + \lambda F_0$. We observe that in general there is no guarantee that $\text{rng } L$ is invariant w.r.t. the evolution $t \mapsto F(\cdot, \cdot, t)$ given by (8). That is, in general, although $F_0 = Lf_0$, if $t > 0$ there is no image $f(\cdot, t) \in L^2(\mathbb{R}^2)$ such that $F(\cdot, \cdot, t) = Lf(\cdot, \cdot, t)$. We will nevertheless assume that the perceived image for any cortical activation is given by the projection operator (6).

3.3 Discretisation via gradient descent

In order to numerically implement the gradient descent (8), we discretise the initial (square) image f_0 as an $N \times N$ matrix. (Here, we assume periodic boundary conditions.) We additionally consider $K \in \mathbb{N}$ orientations, parametrised by $k \in \{1, \dots, K\} \mapsto \theta_k := (k - 1)\pi/K$.

The discretised lift operator, still denoted by L , then transforms $N \times N$ matrices into $N \times N \times K$ arrays. Its action on an $N \times N$ matrix f is defined by

$$(Lf)_{n,m,k} = \mathcal{F}^{-1} \left((\mathcal{F}f) \odot (R_{\theta_k} \mathcal{F} \Psi^{\text{cake}}) \right)_{n,m} \quad n, m \in \{1, \dots, N\}, k \in \{1, \dots, K\},$$

where \odot is the Hadamard (i.e., element-wise) product of matrices, \mathcal{F} denotes the discrete Fourier transform, R_{θ_k} is the rotation of angle θ_k , and Ψ^{cake} is the cake mother wavelet.

Denoting by $F^0 = Lf_0$, and by $G_0 = L\mu$ where μ is a Gaussian filtering of f_0 , we find that the explicit time-discretisation of the gradient descent (8) is

$$\frac{F^{\ell+1} - F^{\ell}}{\Delta t} = -(1 + \lambda)F^{\ell} + G_0 + \lambda F^0 + \frac{1}{2M} \mathcal{R}_{F^{\ell}}, \quad \Delta t \ll 1, \ell \in \mathbb{N}.$$

Here, for a given 3D Gaussian matrix W encoding the weight ω , and an $N \times N \times M$ matrix F , we let, for any $n, m \in \{1, \dots, N\}$ and $k \in \{1, \dots, K\}$,

$$(\mathcal{R}_F)_{n,m,k} := \sum_{n', m'=1}^N \sum_{k'=1}^K W_{n-n', m-m', k-k'} \sigma(F_{n,m,k} - F_{n',m',k'}).$$

Fig. 1: Grating inductions with varying background orientation.

We refer to [4, Section IV.A] for the description of an efficient numerical approach used to compute the above quantity in the 2D case and that can be translated verbatim to the 3D case under consideration.

After a suitable number of iterations $\bar{\ell}$ of the above algorithm (measured by the criterion $\|F^{\ell+1} - F^{\ell}\|_2 / \|F^{\ell}\|_2 \leq \tau$, for a fixed tolerance $\tau \ll 1$), the output image is then found via (6) as $\bar{f}_{n,m} = \sum_{k=1}^K F_{n,m,k}^{\bar{\ell}}$.

4 Numerical results

In this section we present the results obtained by applying the cortical-inspired model presented in the previous section to a class of well-established phenomena where contrast perception is affected by local orientations.

We compare the results obtained by our model with the corresponding Wilson-Cowan-type 2D model (2)-(3) for contrast enhancement considered in [16,3]. For further reference, we also report comparisons with two standard reference models based on oriented Gaussian filtering. The former is the ODOG model [7] where the output is computed via a convolution of the input image with oriented difference of Gaussian filters in six orientations and seven spatial frequencies. The filtering outputs within the same orientation are then summed in a non-linear fashion privileging higher frequencies. The second model used for comparison is the BIWaM model, introduced in [20]. This is a variation of the ODOG model, the difference being the dependence on the local surround orientation of the contrast sensitivity function⁶.

Parameters. All the considered images are 200×200 pixel. We always consider lifts with $K = 30$ orientations. The relevant cake wavelets are then computed following [2] for which the frequency band \mathbf{bw} is set to $\mathbf{bw} = 4$ for all experiments. In (8), we compute the local mean average μ and the integral term by Gaussian filtering with standard deviation $\sigma_{\mu} > \sigma_{\omega}$. The gradient descent algorithm stops when the relative stopping criterion defined in Section 3.3 with a tolerance $\tau = 10^{-2}$ is verified.

⁶ For our comparisons we used the ODOG and BIWaM codes freely available at https://github.com/TUBvision/betz2015_noise.

Fig. 2: Model outputs of input Fig. 1a. Parameters for (d): $\sigma_\mu = 10$, $\sigma_\omega = 5$, $\lambda = 0.5$.

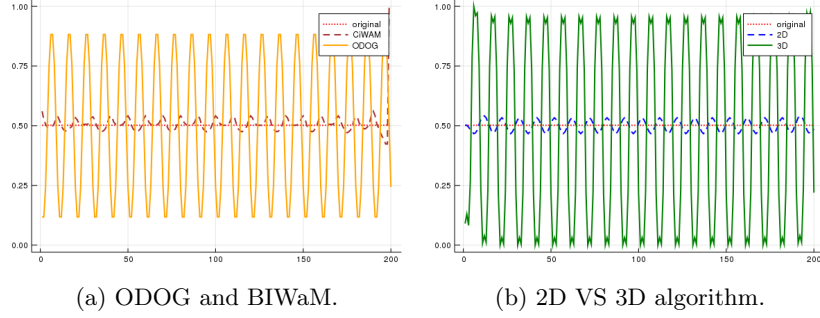

Fig. 3: Middle line-profiles of outputs in Fig. 2.

4.1 Grating induction with oriented relative background

Grating induction (GI) is a contrast effect first described in [18] and later studied, e.g., in [7]. In this section we describe our results about GI with *relative background orientation*, see Figure 1. Here, when the background has different orientation from the central grey bar, a grating effect, i.e. an alternation of dark-grey/light-grey patterns within the central bar, is produced and perceived by the observer. This phenomenon is contrast dependent, as the intensity of the induced grey patterns (dark-grey/light-grey) is in opposition with the background grating. Moreover, it is also orientation-dependent as the magnitude of the phenomenon varies based on the background orientation, and is maximal when the background bars are orthogonal to the central grey one.

Discussion on computational results. We observe that model (8) predicts, in accordance with visual perception, the appearance of a counter-phase grating in the central grey bar, see Figures 2d and 4d. The same result is obtained by the ODOG model, see Figures 2a and 4a. In particular, Figures 3 and 5 show higher intensity profile when the background gratings are orthogonal to the central line, with respect to the case of background angle equal to $\pi/3$, see orange and green dashed line. On the other hand, the BIWaM model and the WC-type 2D model for contrast enhancement do not appear suitable to describe this phenomenon. See for comparison the red and blue dashed lines in Figures 3 and 5.

Fig. 4: Model outputs of input Fig. 1b. Parameters for (d): $\sigma_\mu = 10$, $\sigma_\omega = 5$, $\lambda = 0.5$.

Fig. 5: Middle line-profiles of outputs in Figure 4.

4.2 Poggendorff illusion

The Poggendorff illusion (see Figure 6c) consists in the super-position of a surface on top of a continuous line, which then induces a misalignment effect. This phenomenon has been deeply investigated [24,25] and studied via neuro-physical experiments, see, e.g., [24]. Here, we consider a variation of the Poggendorff illusion, where the background is constituted by a grating pattern, see Figure 6a.

Discussion on computational results. The result obtained by applying (8) to Figure 6a is presented in Figures 6b, 7d. As in Section 4.1, we observe an induced counter-phase grating in the central grey bar. However, the question here is whether it is possible to reconstruct numerically the perceived misalignment between a fixed black stripe in the bottom part of Figure 6a and its collinear prosecution lying in the upper part. Note that the perceived alignment differs from the actual geometrical one: for a fixed black stripe in the bottom part, the alignment of the corresponding collinear top stripe is perceived slightly flushed left, see Figure 6c, where single stripes have been isolated for better visualisation. To answer the question, let us focus on Figure 6b and mark by a continuous green line a fixed black stripe in the bottom part of the image. In order to find the corresponding perceived collinear stripe in the upper part, we follow how the model propagates the marked stripe across the central surface, by drawing a dashed line. As expected, the prosecution provided by the algorithm following this procedure does not correspond to its actual collinear prosecution.

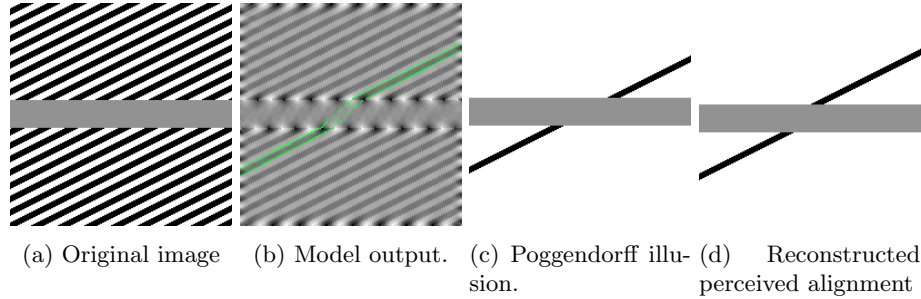

Fig. 6: A variation of the Poggendorff illusion. The presence of the grey central surface in 6a induces a misalignment of the background lines of the output 6b. In 6c, we present the original Poggendorff illusion, extracted from 6a, and in 6d the reconstruction deduced from 6b. Parameters: $\sigma_\mu = 10$, $\sigma_\omega = 3$, $\lambda = 0.5$.

The proposed algorithm hence computes an output in agreement with our perception. Comparison with reference models is presented in Figures 7 and 8. We observe that the results obtained via the proposed 3D-WC model cannot be reproduced by the BIWaM nor the WC-type 2D model, which moreover induce non-counter-phase grating in the central grey bar. On the other hand, the result obtained by the ODOG model is consistent with ours, but presents a much less evident alternating grating within the central grey bar. In particular, the induced oblique bands are not visibly connected across the whole grey bar, i.e. their induced contrast is very poor and, consequently, the induced edges are not as sharp as the ones reconstructed via our model, see Figure 8 for an example on the middle-line profile.

5 Conclusions

We presented a cortical-inspired setting extending the approach used in [4,3] to describe contrast phenomena in images. By mimicking the structure of V1, the model explicitly takes into account information on local image orientation and it relates naturally to Wilson-Cowan-type equations. The model can be efficiently implemented via convolution with appropriate kernels and discretised via standard explicit schemes. The information on the local orientation allows to describe contrast phenomena as well as orientation-dependent illusions, outperforming the models introduced in [4,3]. The introduced mean field model is competitive with the results obtained by applying some popular orientation-dependent filtering such as the ODOG and the BIWaM models [7,20].

Further investigations should address a more accurate modelling reflecting the actual structure of V1. In particular, this concerns the lift operation where the cake wavelet filters should be replaced by Gabor filtering, as well as the interaction weight ω which could be taken to be the anisotropic heat kernel of [11,14]. Finally, extensive numerical experiments should be performed to assess

Fig. 7: Reconstruction of the Poggendorff illusion 6a via reference models.

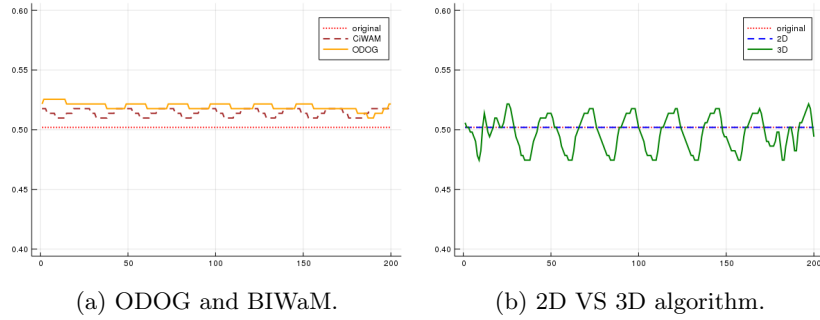

Fig. 8: Middle line-profiles of outputs in Figure 7.

the compatibility of the model with psycho-physical tests measuring the perceptual bias induced by these and other phenomena such as the tilt illusion [23]. This would provide insights about the robustness of the model in reproducing the visual pathway behaviour.
